Quantum States of Confined Carriers in Very Thin 
$\text{Al}_x\text{Ga}_{1-x}\text{As-GaAs-Al}_x\text{Ga}_{1-x}\text{As}$ Heterostructures

Bell Laboratories, Murray Hill, New Jersey 07974
(Received 24 June 1974)

Quantum levels associated with the confinement of carriers in very thin, molecular-beam-grown $\text{Al}_x\text{Ga}_{1-x}\text{As-GaAs-Al}_x\text{Ga}_{1-x}\text{As}$ heterostructures result in pronounced structure in the GaAs optical absorption spectrum. Up to eight resolved exciton transitions, associated with different bound-electron and bound-hole states, have been observed. The heterostructure behaves as a simple rectangular potential well with a depth of $\approx 0.88 \Delta E_g$ for confining electrons and $\approx 0.12 \Delta E_g$ for confining holes, where $\Delta E_g$ is the difference in the semiconductor energy gaps.

One of the most elementary problems in quantum mechanics is that of a particle confined to a one-dimensional rectangular potential well. In this Letter, we report the direct observation of numerous bound-electron and bound-hole states of rectangular potential wells, formed by a thin layer of GaAs sandwiched between $\text{Al}_x\text{Ga}_{1-x}\text{As}$ slabs. The levels are observed by measuring the optical absorption of the central GaAs layer of the structure. The presence of the bound states introduces a series of resolved exciton transitions in the above-band-gap absorption spectrum of GaAs layers less than 500 Å thick. A range of heterostructures, with central GaAs layers as thin as 70 Å, has been studied. The heterostructures produce two attractive potential wells of different depths, one for electrons and one for holes. Analysis of the spectra shows that the wells are extremely rectangular and that the electron and hole well depths are approximately 88 and 12% of $\Delta E_g$, respectively.

The investigation was made possible by two recent developments. The first is the emergence of molecular-beam epitaxy (MBE) as a technique for the growth of layers of III-V semiconductors. Our observations demonstrate the great precision of MBE in fabricating thin and uniform layers. The second is the development of selective chemical etches for the removal of the GaAs substrate without damaging the thin epitaxial layers of the heterostructure.

During the last decade there has been intense activity in the study of electrons confined to thin layers. These studies were primarily experiments on metals, superconductors, and metal-oxide-semiconductor devices. Recently, Chang, Esaki, and Tsu reported observing two levels in tunneling experiments involving GaAs-Al$_x$Ga$_{1-x}$As heterostructures, grown by MBE, with GaAs thicknesses of 40–50 Å. This confining layer is thinner than any we have studied and in their experiment the applied electric field distorts the rectangular well into a trapezoidal shape. Nevertheless, the energies they quote are consistent with our more detailed observations.

With the use of MBE, the precision growth of multilayer GaAs-Al$_x$Ga$_{1-x}$As heterostructures has been possible. The usual growth conditions are as follows: vacuum before growth, $\approx 1 \times 10^{-9}$ mm; vacuum during growth, $\approx 1 \times 10^{-5}$ mm (ar-
sentic; As,

source; \{100\} GaAs substrate; temperature, 600°C; and semi-automatic shuttering on the Al oven. At our growth rate, 1 \(\mu\)m per hour, the shutter time is equivalent to \(\sim 0.5\) \AA{} of growth. To increase the GaAs optical absorption, as many as fifty GaAs layers have been grown in a single structure. These GaAs layers are separated by Al\(_8\)Ga\(_{1-8}\)As layers which are normally \(\sim 250\) \AA{} thick. The observed bound states penetrate only about 25 \AA{} into the Al\(_8\)Ga\(_{1-8}\)As layers. Consequently, the carriers are tightly bound to individual layers. Hence, we are studying energy levels of a single well, not energy bands of a superlattice. Although it is not possible to measure the electrical properties of the layers themselves, thicker layers, grown under identical conditions, are \(p \sim 10^{16} - 10^{18} \text{ cm}^{-3} \) (GaAs) and \(p \sim 10^{15} - 10^{17} \text{ cm}^{-3} \) (Al\(_8\)Ga\(_{1-8}\)As). As a consequence of the \(\sim 0.12\Delta E_z\) discontinuity in the valence band, the Al\(_8\)Ga\(_{1-8}\)As layers will be depleted. Band bending of 1–10 meV in the Al\(_8\)Ga\(_{1-8}\)As layers, caused by this depletion, should have a negligible effect on the energy levels. This was confirmed by the fact that the spectral features did not change when the thickness of the Al\(_8\)Ga\(_{1-8}\)As layer was varied from 125 to 500 \AA{}. Most data to be discussed here were obtained from structures with \(x = 0.2 \pm 0.01\).

If a particle is completely confined to a layer of thickness \(L_z\) (by an infinite potential well) then the energies of the bound states are

\[
E = E_n + \left(\frac{\hbar^2}{2m}\right)\left(n_x^2 + n_y^2 + n_z^2\right),
\]

where

\[
E_n = \left(\frac{\hbar^2 n^2}{2m}\right)\left(n/L_z\right)^2, \quad n = 1, 2, 3.
\]

In reality the potential well is finite and the above solutions are inadequate for a quantitative analysis of the data. We have used a computer to obtain the eigenvalues for a well depth \(V_0\). The behavior of energy levels relative to those obtained for \(V_0 = \infty\) is shown in Fig. 1. Both the level spacing and the number of bound states decrease as \(V_0\) is decreased, but the \(n = 1\) state exists for all positive values of \(V_0\). Thus, for all attractive potential wells, at least one bound state will exist for each type of carrier.

There will be two series of bound-hole states associated with the \(\pm \frac{1}{2}\) and \(\pm \frac{3}{2}\) valence bands, quantized in the \(z\) direction. We will refer to these as the states of the heavy and light hole. The appropriate masses for calculating these states are \((\gamma_1 - 2\gamma_2)^{-1}m_0 = 0.45m_0\) and \((\gamma_1 + 2\gamma_2)^{-1}m_0 = 0.08m_0\), respectively. These masses determine the \(k_z\) (001) dispersion of these bands. Coulomb attraction correlates the motion of the carriers in \(x\) and \(y\) directions, forming exciton states with peaks in the optical absorption spectrum. States with the same quantum number \(n\) have a substantially greater electron-hole overlap. Consequently, excitons with these states will dominate the optical absorption spectrum. Therefore we expect two series of exciton peaks, one series associated with equal-\(n\) states of the electron and the heavy hole and one series associated with equal-\(n\) states of the electron and the light hole.

Figure 2 displays typical absorption spectra of our structures in the band-edge region of GaAs at 2 K. Roughening the external surfaces with an etch removed all structure due to interference effects. There is negligible absorption in the Al\(_{8.2}\)Ga\(_{0.8}\)As layers below 1.75 eV. The trace labeled \(L_z = 4000\) \AA{} is typical of high-purity bulk GaAs and it shows none of the quantum effects central to this paper. It does, however, show the dominant excitonic\(^8\) contribution to the bulk GaAs band-edge absorption. The traces \(L_z = 210\) \AA{} and \(L_z = 140\) \AA{} show well-developed structure above the usual GaAs band gap. Moreover, the exciton peak of bulk GaAs moves smoothly to higher energy as \(L_z\) is reduced below 500 \AA{},

\[\text{FIG. 1. Calculated energy levels of a particle in a symmetrical rectangular potential well of depth } V_0.\]
FIG. 2. Typical absorption spectra at 2 K. The traces labeled $L_z = 210 \text{ Å}$ and $L_z = 140 \text{ Å}$ show excitons associated with the electron and hole, each in the $n$th bound state. For $L_z = 400 \text{ Å}$, the absorption coefficient $\alpha$ (cm$^{-1}$) is about $2.5 \times 10^4$ at the exciton peak and $\approx 1 \times 10^4$ in the band-to-band region. Similar values are obtained for the thinner multilayers.

FIG. 3. The data points are a plot of the measured $L_z$ versus the measured exciton energies. The open circles are resolved excitons associated with the light-hole $n = 1$ state. The open squares are the extrapolated energies for $n = 0$. The solid curves are the calculated energies for the excitons associated with the electron and heavy hole, each in the $n$th bound state.

thereby becoming the lowest absorption feature in the quantum limit. The faint doubling of the lowest peak in the $L_z = 140-\text{Å}$ spectrum is real. This splitting increases as $L_z^{-2}$ and results in two resolved peaks in thinner layers. No doubling is observed for $n = 2$ peak.

The single exciton series and the doubling of the lowest peak can be explained by assuming that the potential well for holes is weak. Then for layers with small $L_z$, for which two exciton series could be resolved, there is only one bound state for the light holes and consequently only the lowest exciton peak will double. The well depth for holes was determined by fitting the splitting of the lowest peak in a series of samples (see Fig. 3). It was found to be about 28 meV or $\approx 12\%$ of $\Delta E_g$. In making this fit, the known heavy- and light-hole masses and the measured $L_z$ were used. The well depth for electrons must therefore be about 0.88$\Delta E_g$ = 220 meV.

Figure 3 is a plot of $L_z$ versus the measured exciton energies. $L_z$ was determined, within $\pm 10\%$, from the measured rate of growth of the epitaxial layer. The solid theoretical curves were constructed from the known electron mass $m_e = 0.0665 m_0$, the known heavy-hole mass, and the known well depths. Absolute energies were determined by extrapolating the measured ener-

gies to $n = 0$. These extrapolated energies are shown by the open squares. The calculated energies of the bound states for $n = 1, 2, \ldots$ were then added to these energies. The excellent agreement between theory and experiment is a confirmation that the well depths and masses are correct and that the potential wells are quite rectangular. By varying the depth of the potential well for electrons, we found that a depth of 220 ± 30 meV was required to fit the data in Fig. 3, confirming the value deduced above. Attempts to fit the energies with eigenvalues of nonrectangular wells indicated that the potential step forming the side of the well occurs in less than 5 Å.

The energy of the open squares in Fig. 3 is equal to the band-gap energy of GaAs minus the exciton binding energy. The energy of the squares decreases slowly with $L_z$ and eventually saturates at $L_z < 200 \text{ Å}$ at $1.512 \pm 0.001$ eV, about 3 meV below the bulk exciton energy of 1.515 eV (2 K), indicating that the exciton binding energy increases from 4 meV to $\sim 7$ meV as a consequence of carrier confinement. This increase in binding energy agrees quite well with that expected$^{16}$ for a three-dimensional exciton as it approaches the two-dimensional limit.

The spectral dependence of the Auger component of the uv photoemission and the far–uv reflectance show that the optical excitation of 5d core states cannot be described in terms of simple density of states indicating that matrix element effects must be included.

We report ultraviolet–photoelectron–spectroscopy data (24 eV < hv < 30 eV) for Bi₅Te₃ which contain information on optical transitions from 5d core states to conduction band states below the direct emission threshold. The emission in this photon energy range has a strong component resulting from energetically allowed Auger decay of core holes. Similar to previously reported works on other solids, the spectral dependence of Auger emission is found to exhibit the same features as the optical–reflectance spectra. The central issue of this Letter is the evidence that the structure in both Auger and reflectance spectra cannot be explained in terms of a simple density–of–states model despite the fact that the initial state can be considered a core state. That is, the structure in the two spectra does not reflect directly the spin–orbit splitting of the 5d₃/₂ and 5d₅/₂ core states, a fact which indicates the effect of matrix elements on core excitation. This finding should also be of importance to soft–x–ray absorption spectroscopy.

A detailed description of the photoemission spectrometer, which utilizes the UWPSL 240–MeV storage ring, has been given elsewhere. The overall energy resolution and the signal–to–noise ratio were better than 0.2 eV and 100:3, respectively. Rhombohedral (space group D₃h³) single crystals of Bi₅Te₃ were grown from the 99.9999% purity elements using a previously described technique. Bi₅Te₃ is a strongly anisotropic semiconductor (band gap E₉ ~0.15 eV) of layered structure which results in excellent quality of in situ (~5×10⁻¹⁰ Torr) cleaved surfaces.

The photoemission energy distribution curves (EDC’s) are first used (Fig. 1) to determine the
